Beta-blockers in the third millennium - when are they really indicated

Prichard BNC, Cruickshank JM, Graham B
Beta-blockers in the Third Millennium – When are They Really Indicated?

B. N. C. Prichard, B. Graham, J. M. Cruickshank

Beta-blockers have come a long way in development since the first two used clinically, pronethalol and propranolol, were evaluated in angina pectoris, cardiac arrhythmias and phaeochromocytoma. Pharmacological development has been directed to improving both selectivity and more recently agents with additional vasodilator activity, either by alpha-receptor blockade or by other mechanisms. Therapeutic development has led to the use of beta-blockers in a wide variety of indications, principally in the cardiovascular system, but also elsewhere.

Numerous studies have confirmed the value of beta-blockers in ischaemic heart disease. They remain a most efficacious treatment for symptom relief in angina pectoris although evidence that prognosis is improved is mainly indirect. Many studies have demonstrated that beta-blockers improve prognosis post myocardial infarction; benefit being demonstrated in many categories, particular value has been shown in patients with poor left ventricular function.

The first non-predicted use of beta-blockers demonstrated was their antihypertensive effect. They are now accepted by major international guidelines as first line therapy. Beta1-selective agents are more effective than non-selective agents, and contrary to some earlier evidence based on non-selective agents, they are often effective in younger (under 65) black patients. Beta-blockers have been shown to improve prognosis in younger patients while in the elderly, diuretics appear superior in primary prevention.

Since early reports of propranolol precipitating heart failure, studies with bisoprolol, carvedilol and metoprolol have established that beta-blockers carefully titrated even when added to a treatment regimen including ACE-inhibitors give a dramatic improvement in survival. Diabetes was another area where beta-blockers were considered to have disadvantages. While beta2-blockade should be avoided in patients on insulin, hypoglycaemic episodes are not rendered more of a problem by beta1-selective blockade. A recent important study in type 2 diabetes has shown that tight control of blood pressure resulted in an improvement of various prognostic indicators, with results with atenolol treated patients throughout being at least as good as with the captopril treated subjects.

Some supposed contra-indications to beta-blockade have been previously over-emphasised. Notably, patients with chronic airways obstructive disease frequently tolerate beta-blockade well and will benefit, eg, post infarction, although beta1-selective agents should be used. Quality of life investigations show that beta1-selective drugs are well tolerated when compared to other drugs including ACE-inhibitors. J Clin Basic Cardiol 2001; 4: 3–9.

Key words: beta-blocker, morbidity, mortality, diabetes, hypertension

Beta-adrenergic blocking drugs were conceived by Sir James Black when he reasoned that a drug to inhibit the effect of sympathetic nerve stimulation and catecholamines on the heart would be valuable in angina pectoris, arrhythmias and phaeochromocytoma. Papers describing the first beta-blocker pronethalol reported initial clinical trials in this area [1]. Since the early 1960's there has been continuing progress in the field of beta-blockade, now therefore for over 35 years, both in terms of pharmacological development and in the wider appreciation of the clinical application, with continuing interesting developments [2].

The beta-adrenergic blocking drugs differ in various aspects. Non-selective agents blocking both beta1-receptors, eg at sympathetic innervation of the heart, and beta2-receptors, eg in bronchial and vascular smooth muscle. Propranolol, the archetypal agent, also has membrane stabilising activity or local anaesthetic effects, though this property does not contribute to its therapeutic effects. Propranolol is a pure antagonist, whereas drugs like pindolol besides blocking the beta-receptor also have some stimulatory action, ie partial agonist effect.

A major thrust of development of beta-blockers has been the search for and the introduction of agents with increasing selectivity for the beta1-receptor, in contrast to their lesser effect on the beta2-receptor. The beta1-receptor mediates the effects of sympathetic nerve stimulation completely, and circulatory catecholamines mostly, on the heart and renin release, whereas the beta2-receptor mediates bronchial and vascular dilatation [1]. Drugs with other properties have also been introduced such as alpha1-blocking activity, eg carvedilol, a non-selective blocker which also has an anti-oxidant [3], or nebivolol, a highly selective beta1-selective agent which has a nitric oxide dependant vasodilator property [4]. It seems that the therapeutic use of beta-blockers resides in their beta1-blocking action.

Therapeutic Use of Beta-Blockers

Black originally suggested that beta-blockers would be clinically useful in conditions where the effect of the sympathetic nerves to the heart and the action of circulatory catecholamines was deleterious, notably angina pectoris, arrhythmias and phaeochromocytoma. Studies with the first clinically evaluated beta-blocker pronethalol (reported in 1963) confirmed this prediction [1]. Sympathetic stimulation was known to increase the gradient in congenital outflow tract obstruction and propranolol, the first widely evaluated beta-blocker, was found to inhibit the increase. An important further development was the first study which suggested that propranolol reduced mortality after myocardial infarction [5].
There have also been developments in the use of beta-blockers which were surprising, a theme recently taken up by Cruickshank [2], describing some recent developments. Firstly, the initial report that beta-blockers lowered the blood pressure came in 1964 [6]; this effect had not been seen to animal experiments and as beta-blockers increased peripheral resistance, for some time there was resistance to the concept of the use of beta-blockers in hypertension [7]. Even more surprising has been the development and establishment of beta-blocking drugs as very valuable drugs, improving prognosis, in the treatment of heart failure, particularly as if anything other than very small doses are given initially acute heart failure is readily precipitated, as was reported in 1965 [8], as would be expected from interfering with the body’s compensatory mechanism, an increase in heart rate, for the failing pump.

Besides the main indication of beta-blockers in ischaemic heart disease, hypertension and heart failure, beta-blockers have been assessed in a wide variety of conditions. In addition to arrhythmias and phaeochromocytoma other cardiovascular applications include congenital heart disease, notably Fallot’s and hypertrophic subaortic stenosis, congestive cardiomyopathy, dissecting aneurysm, portal hypertension, mitral stenosis, hyperkinetic heart syndrome [1]. Beta-blockers have also been used in thyrotoxicosis, locally in glaucoma, tremors, anxiety with somatic manifestations, drug withdrawal, and as a prophylactic for migraine [1].

**Ischaemic heart disease**

**Angina pectoris**

Beta-blockers reduce heart rate, the principal determinant of myocardial oxygen consumption, and the velocity of cardiac contraction, and as the former predominates there is longer time for diastolic filling. Blood pressure is reduced modestly in normotensives at rest, on exercise, and the tachycardia to a wide variety of sympathetically stresses is inhibited. There is therefore, by the above mechanism, a delay in the moment of imbalance between oxygen supply and oxygen used and the production of ischaemia and the symptoms of angina pectoris [1].

Beta-blocking drugs are generally very effective in the relief of symptoms of angina. A clear dose response relationship was shown in a five-way cross over log-dose response study of propranolol on symptom relief. There was increasing relief compared to placebo as dosage was increased from a daily average of 52 mg, to 104 mg, 208 mg and 417 mg [9]. There is little convincing evidence of differences between various beta-blockers [1], at least in part due to difficulties in performing meaningful comparisons, particularly with drugs that are liver metabolised which therefore display varying blood levels to a given dose. However, in a variable dose cross over comparison of propranolol which is devoid to partial agonist activity, with practolol which has considerable partial agonist activity, propranolol was found to be superior in terms of reduction of angina attacks and trinitrate consumption [10]. Likewise atenolol was found more effective than practolol and also in terms of exercise tolerance [11]. Atenolol has also been found significantly more effective in reducing angina attacks than pindolol which also possesses partial agonist activity [12]. The vasodilatory beta-blocker is also effective, prolonging exercise tolerance, but there is no evidence that it is more effective than other beta-blockers [13].

**Combination treatment in angina**

From the very earliest studies of beta-blockers in angina they have been used in combination with glyceryl trinitrate for the acute attacks of anginal pain, their coronary vasodilatory effect and preload reduction being a totally different mode of action to beta-blockade. There is evidence that the longer acting nitrate, isosorbide, added to beta-blockade increases exercise tolerance [14] or gives additional relief of angina symptoms [15], even if not so effective as nifedipine [16].

Beta-blockers combine well in the symptomatic relief of angina with dihydropropyridine calcium antagonists [17], e.g. nifedipine, with greater relief from propranolol and nifedipine in combination than either agent alone [18]. In one large study (total n = 551) verapamil, and amloidipine plus atenolol reduced the number of ischaemic episodes with Holter monitoring, whereas amloidipine alone force-titrated to 10 mg/day resulted in significantly more ischaemia than placebo. All three active treatments increased acute exercise tolerance compared to placebo [19]. While intravenous use in combination is best avoided because of the possible development of heart block, the combination of propranolol and verapamil was noted to give a greater increase in exercise tolerance over placebo than either drug alone [20]. Similar observations have been made with a combination with diltiazem [21].

**Indication for beta-blockers in angina**

Besides being a most efficacious group of drugs in the relief of symptoms of angina pectoris [13], they may improve prognosis. There are no long term mortality studies in angina, the rationale for supposing a possible benefit comes mainly from studies post myocardial infarction [22–24]. It has been shown that the beta-1-selective bisoprolol reduces mortality in high risk patients with evidence of myocardial ischaemia on wall motion studies with dobutamine undergoing major vascular surgery. Cardiac death rate in the bisoprolol group (n = 59) was 3.4 %, 17 % in the standard care group (n = 52) (p = 0.02). The incidence of non-fatal myocardial infarction was 0 % and 17 % respectively (p < 0.001) [25].

A follow up of the total ischaemic burden bisoprolol study (TIBBS) in patients with angina pectoris found that those patients in the 8 week study randomised to bisoprolol had a total event rate (death, acute myocardial infarction, hospital admission for unstable angina pectoris) after 1 year open follow up, of 22.1 %, compared to an event rate of 33.1 % in those patients who received nifedipine for the initial eight weeks. At one year with the physician able to change treatment, beta-blockers were still being used in 47 % of the bisoprolol group, in 32 % of the nifedipine group (p = 0.008), whereas the figures for calcium antagonists were 21 % and 26 % respectively [26].

**Myocardial Infarction**

Beta-blocking drugs are well established as agents that reduce mortality post myocardial infarction [1, 27]. Non-selective and beta-1-selective agents appear to be of similar efficacy but agents that possess significant partial agonist effect, intrinsic sympathomimetic action, are less effective [27]. The class III anti-arrhythmic activity which is possessed by the beta-blocker sotalol is no advantage; sotalol itself only gives a modest non-significant reduction in mortality post infarction [28] while the non-beta-blocking d-isomer of sotalol, which just possesses the class III anti-arrhythmic effect increases mortality by 65 % [29].

Pooled results of 28 placebo controlled trials of beta-blockers given intravenously soon after the onset of myocardial infarction indicate an average reduction of mortality of 13 % [27], long term studies (n = 24) indicate a reduction of about 20 % [27, 30]. An important contributor to the fall in mortality is reduced sudden death [30, 31].
Most beta-blocking studies post infarction were performed prior to the use of thrombolysis, aspirin and ACE-inhibitors, however there is evidence that beta-blockers should still be administered as part of current treatment [30]. Beta-blockers given acutely shortly after hospital admission to thrombolysed patients reduced re-infarction rate by 48 % compared to those where beta-blockade was delayed by one week [32]. In the TEAHAT study [33] the best effect of re-PA on infarct size was seen in patients who were also given metoprolol. Beta-blockers added to ACE-inhibitors in patients with ventricular dysfunction improve prognosis [34], and in the US heart failure study with carvedilol added to ACE-inhibition the incidence of sudden death was reduced by 50 % [35]. Gottlieb et al. [36] recently reported a most interesting survey of post infarction beta-blockade usage in over 200,000 patients. They reported benefit regardless of systolic blood pressure, age, ejection fraction or even in patients with co-existent chronic obstructive pulmonary disease, often regarded as a contra-indication to beta-blockade (Table 1).

**Hypertension**

Beta-blockers were only slowly accepted as treatment for hypertension [7] and even seven years after the first reports of the hypotensive effect of pronethalol [6] and propranolol [37, 38] some concluded that because of the reduction in cardiac output and the rise in peripheral resistance, beta-adrenergic blocking drugs should not be used routinely in the treatment of hypertension [38]. Beta-blockers are now regarded as a first line choice of treatment in hypertension along with diuretics, by the Joint National Committee [39], the British Hypertension Society [40] and a first line alternative with various antihypertensives by WHO/ISH [41].

**Efficacy**

While the mode of action of beta-blockers in hypertension is still not clear, it does seem to be a function of beta1-blockade [1, 42]. It was noted in the early evaluation of beta-blockade that adrenaline in the presence of beta2-blockade resulted in a greater rise of blood pressure because its beta2-vasodilator action, previously partially offsetting its alpha-vasoconstrictor effect, is inhibited [43]. It is possible therefore that beta2-blockade antagonises the modest background vasodilator effect of circulating adrenaline, which reduces the fall in blood pressure seen with beta1-blockade. This may be the reason that a 2–3 mmHg greater fall in blood pressure is seen with beta1-blockade compared to non-selective blockade. It has been found that no fall in blood pressure is seen with selective beta2-blockade (ICI 118 551) [1].

Several large clinical trials have shown that beta-blockers, atenolol [44–46] or acebutolol [47] are similar in antihypertensive effect to examples from the major classes of hypotensive drugs. In a large survey of veterans hypertension clinics it was found that blood pressure control with beta-blockers was similar to other agents, with or without a diuretic [48].

Bisoprolol was possibly the most beta1-selective agent generally available [49]. There is some suggestion that bisoprolol may control hypertension more effectively than atenolol [49–51]. Nebivolol is even more selective, but as yet there is only limited data comparing it with other beta-blockers [4].

**Combination treatment in hypertension**

Combination versus single drug regimens are valuable in the treatment of hypertension [52, 53]. A large factorial study involving a total of 512 patients utilised bisoprolol 2.5 mg, 10 mg or 40 mg, hydrochlorothiazide 6.25 mg or 25 mg, and placebo, given in all possible combinations [54]. Blood pressure was lowered to less than 70 mmHg diastolic in 61 % of patients by the combination of bisoprolol 2.5 mg and hydrochlorothiazide 6.25 mg. In another study the value of bisoprolol 5 mg and hydrochlorothiazide 6.25 mg was confirmed [55], and Prisant et al. [56] reported that the combination with low dose hydrochlorothiazide controlled blood pressure to a similar extent to amlopidine, while each treatment was more effective than enalapril.

**Effect of age and race on the antihypertensive effect of beta-blockers in hypertension**

There have been suggestions that the response of blood pressure to beta-blocking drugs in the elderly and blacks was poor, although much of the evidence which led to this view was based on studies with non-selective beta-blockers [1].

In the study of bisoprolol, hydrochlorothiazide and the combination of the two, Frishman et al. [55] reported no reduction in the fall of blood pressure in those patients over 60 years compared to those below that age with bisoprolol alone or the combination of bisoprolol and hydrochlorothiazide. The double blind parallel group study of six different antihypertensive regimens [44, 45] did not find any age-related response to atenolol in white patients, 65 % below 60 years old were successfully controlled compared to 72 % of those over 60 years.

Jamerson and DeQuattro [57] analysed thirteen clinical trials in African Americans published between 1988 and 1993. They found less reduction of blood pressure with ACE-inhibitors and beta-blockers in contrast to diuretics and calcium channel blockers. Materson et al [44, 45] observed that blacks under 60 showed a 51 % response rate to atenolol, only exceeded by diltiazem. However, in the over 60’s blacks, a better response rate was obtained with diltiazem 85 %, hydrochlorothiazide 64 %, clonidine 58 % and prazosin 49 %.

Primary prevention in hypertension

Several prospective trials have shown that diuretics and beta-blockers reduce the development of complications of hypertension, most clearly seen with stroke and heart failure, less clear with coronary heart disease [58, 59]. When data in men under age 65 from the Medical Research Council [60] and the IPPPSH [61] studies were grouped to compare diuretic and beta-blocker treatment, non selective propranolol and oxprenolol respectively, it was found with beta-blockade there was a 28% lower cardiovascular mortality (p = 0.03), 21% lower non-fatal plus fatal coronary heart disease (p = 0.04), while total mortality also showed a trend to be less on beta-blockade (18%, p = 0.09) [62]. The HAPPY trial with the beta1-selective agents metoprolol and atenolol, versus

There are various possible mechanisms for benefit in [35]. There are various possible mechanisms for benefit in [74]. The combined US carvedilol studies suggested a 65% reduction in mortality in patients with heart failure [63], while in the metoprolol arm of the study with a 14 month extension, MAPHY, beta-blockade gave a lower mortality [64]. It should be noted that benefit in the MAPHY study with a beta1-selective agent was seen in both smokers and non-smokers. Miell and Greenberg [65], in a further analysis of the MRC 1985 study, reported that Q wave myocardial infarction and sudden death in men and women combined, was significantly less with propranolol compared to diuretic treatment. It appears with non-selective blockade with propranolol [60] that benefit was seen in non smoking men whereas in the MAPHY study [64] benefit was also seen in non smokers but was more marked in smokers.

However, in the MRC study in the elderly, diuretics were found to be superior to beta-blockers in primary prevention in hypertension, both in terms of reducing the manifestation of coronary and cerebrovascular disease [66, 67]. It should be noted, however, in the MRC study 63% of the patients randomised to beta-blockade were lost to follow-up. The difference in the elderly may be due to several factors. Ageing is associated with a loss of compliance, this is not favourably influenced by beta-blockade [68]. Also hypertension in the elderly is associated with low renin levels and low sympathetic activity.

Heart failure

As sympathetic mediated tachycardia was an important compensatory mechanism for the failing heart, heart failure was regarded as an important contra-indication for a beta-blocking drug. Indeed the first case of heart failure precipitated by propranolol was reported in 1964 [37]. However, it is now clear that provided the initial doses are small and are then titrated carefully beta-blockade, even when added to a regimen of diuretics and ACE-inhibitors, improves the prognosis [69-71].

Beta1-selective agents are effective in severely ill patients, as demonstrated in CIBIS II [72] in NYHA Class III (88%) and Class IV (17%) (n = 264). There was a 34% reduction in mortality with bisoprolol slowly titrated up to 10 mg, compared to placebo. Benefit in this study, seen in both ischaemic and non-ischaemic patients was due to a reduction in sudden death. Similarly a study with delayed release metoprolol, MERIT-HF [73], reported a 34% reduction of mortality, in patients with an ejection fraction less than 40%. In this study there was both a reduction in sudden death (41%) and progressive heart failure (49%). Carvedilol is a non-selective beta-blocker which also has weak a1-blocking properties and anti-oxidant activity, several studies have shown that carvedilol reduces mortality in patients with heart failure [74]. The combined US carvedilol studies suggested a 65% reduction in mortality in patients treated with carvedilol [35]. There are various possible mechanisms for benefit in heart failure, beta1-blockade appears to be the important pharmacological effect [75]. Bradycardia allows for longer for diastolic filling and reduces cardiac oxygen consumption. There is an inhibition of cardiac adrenergic drive. Sympathetic stimulation is initially supportive but later is damaging to the failing heart. Beta-blockade also has an anti-arrhythmic effect, catecholamine myocardial toxicity is inhibited; concentrations of noradrenaline that can be found in the human heart in heart failure cause cardiac myocyte injury. In heart failure there is selective down regulation of beta1-subtype, beta-blockade restores the population of beta1-receptors and there is enhanced coupling to stimulatory G protein.

There remain questions to be answered [76]. The COMET study (Carvedilol or Metoprolol European Trial) will address the question of whether the benefits of beta-blocking agents in heart failure is a class effect. The COPPERNICUS study is further assessing carvedilol in severe heart failure, while CARMEN will study the question do beta-blockers improve cardiac structure and function in patients with heart failure not receiving ACE-inhibitors. CAPRICORN will examine the question does carvedilol improve prognosis of myocardial infarction in the presence of ACE-inhibition.

Diabetes

The co-existence of diabetes, particularly with hypertension where there are several alternative treatments, has been considered a relative contraindication for beta-blockade [1]. Cruickshank [2] has recently discussed the responsible factors for this view. Recently, however, studies have reported that mortality and re-infarction rates in survivors of myocardial infarction who were also diabetic benefit from beta-blockade, at least to a similar degree as non-diabetics [31, 77].

The incidence of hypoglycaemic episodes is a matter of considerable importance in the day-to-day control of diabetes. Shorr et al. [78] reported that, although numbers were not large, the incidence of hypoglycaemic episodes in a series of hypertensive diabetics treated with beta1-selective agents (488 patient years) was not more than with ACE-inhibitors (1009 patient years), calcium channel blockers (1505 patient years) or thiazides (5098 patient years). Non-selective beta-blockers can delay the recovery of blood pressure and could potentiate a hypoglycaemic episode. During hypoglycaemia they can result in a rise in blood pressure with reflex bradydycardia, consequent on the beta2-mediated block of the vasodilator effect of circulating adrenaline. The rise can be severe. Beta2-blockers should be therefore avoided in patients being treated with insulin [2].

There have been very informative recent UKPDS studies in diabetic type II hypertensive patients. It was found that tight control of the blood pressure with atenolol or captopril aiming for less than 150/85, achieving 144/82 mmHg (n = 758), when compared to less tight control with other drugs aiming for less than 180/105, achieving an average of 154/87 mmHg with an 8.4 year follow-up, gave a wide range of improved outcomes. There was a reduction in deaths related to diabetes (OR 0.68, CI 0.49–0.94), in strokes (OR 0.56, CI 0.35–0.89), in microvascular disease (OR 0.63, CI 0.44–0.89) and any diabetes-related end point (OR 0.76, CI 0.62–0.92). There were non-significant trends in favour of light control with all cause mortality, myocardial infarction and peripheral vascular disease [79]. Additionally there was a 50% reduction in the incidence of heart failure, 34% reduction in worsening retinopathy, 47% reduction in loss of visual activity, and a 29% reduction in the risk of urinary albumin excretion (all with p values better than <0.01).

In a comparison of the drugs used to achieve tight control of the blood pressure it was found that a BP 143/81 mmHg

FOCUS ON BETA-BLOCKERS

J Clin Basic Cardiol 2001; 4: 6

When are Beta-Blockers Indicated?
FOCUS ON BETA-BLOCKERS

When are Beta-Blockers Indicated?

was achieved with atenolol 50 or 100 mg OD (n = 358) and with captopril 144/83 mmHg; 25 or 50 mg bd (n = 400) [80]. There was a non-significant trend in favour of atenolol with any diabetes endpoint, deaths due to diabetes, all cause mortality, myocardial infarction, stroke, peripheral vascular disease and microvascular disease, besides heart failure and sudden death. A higher glycaemic haemoglobin for the first four years was seen with atenolol but not for the last five years of the study. The incidence of hypoglycaemic problems did not differ. Compliance was similar for the first four years but then it was 80 % for captopril, 74 % for atenolol in terms of patient years follow-up (p = 0.0001). This was mainly the result of bronchospasm (6 %) and claudication or cold feet (4.9 %) on atenolol, offset to some degree by cough (4 %) on captopril.

The mechanism of benefit from beta-1-blockade may be that in type 2 diabetes the high insulin levels stimulate noradrenaline release [81, 82]. This consequent increased sympathetic activity with the various possible complications [83] can be inhibited by beta-1-blockade.

Chronic obstructive pulmonary disease

Patients who have even relatively severe chronic obstructive pulmonary disease can tolerate beta-blockers well, and its coexistence should not be regarded as a contra-indication to beta-blockade use. A beta-1-selective agent should be used as if there is a beta-responsive component, then less block will occur and the patient will respond to beta2-bronchodilatation even if larger than normal doses are needed [1]. As discussed above in a large survey of patients post-myocardial infarction and co-existent chronic obstructive pulmonary disease benefit in terms of improved survival at least as much as patients without this complication [36].

Peripheral vascular disease

Beta-blockers are well recognised to cause cold extremities. A beta-1-selective drug or an agent with partial agonist activity might then be regarded as a better choice. In the absence of peripheral vascular disease effect of beta-blockers on the peripheral circulation is not otherwise important. In patients with severe peripheral vascular disease beta-blockers should only be used with great care. In less severe occlusive disease beta-blockers did not have important effects on the peripheral circulation and may even improve flow, by a reversed steal effect, to the diseased area [1, 84].

Lipids

Beta-blockers, at least the non-selective drugs without partial agonist activity, increase triglyceride levels, 20–50 %, and lower HDL-C levels, 10–20 %. The beta-1-selective agents have lesser effects, they overall decrease HDL-C by 7–10 %, increase triglycerides 10–20 %. Drugs with marked partial agonist activity such as pindolol have little effect on lipids, least effect being from a selective agent which also has agonist activity [85–87]. The mechanism of triglyceride increase with non-selective beta-blockade may be that α-stimulation unopposed by beta2-adrenergic activity reduces lipoprotein lipase activity. Less effect would be expected from beta-1-blockade, or indeed with non-selective blockade plus α-blockade as has been recorded with labetalol. The reduction of lipoprotein lipase action reduces catabolism of triglycerides and VLDL. Triglyceride and cholesterol ester exchange between VLDL and HDL leads to triglyceride enrichment of HDL, and increased catabolism of HDL-C [87].

Notwithstanding any effect beta-blockers may have on the lipid profile, it has not prevented them from being useful in the long-term treatment of various cardiovascular disorders.

Quality of life

Croog et al. [88] compared propranolol, methyldopa and captopril, and found that captopril resulted in a better quality of life compared to propranolol, in turn better than methyldopa. However, what was observed with the non-selective lipid soluble propranolol was not the same with all beta-blockers. It was later found that the beta1-selective atenolol had a similar quality of life score to ACE-inhibitors [89], while the non-selective propranolol was found to have a poorer global score, in accord with the findings of Croog et al. [88]. Others have confirmed that atenolol was similar to captopril [90]. Fletcher et al. [91], in a large double-blind randomised parallel group study, observed that the ACE-inhibitor cilazapril and atenolol had a similar quality of life assessment, both superior to nifedipine. The highly selective beta-1-selective bisoprolol was found to be similar to enalapril [92]. The combination of low dose (6.25 mg) hydrochlorothiazide and bisoprolol was reported to have a similar quality of life to amlodipine with a trend to be better than enalapril [49]. The TOMHS study showed that amlodipine and chlorthalidone were significantly better than placebo in a global assessment of the various measures of quality of life, while doxazosin and enalapril did not differ from placebo and amlodipine just failed to reach accepted level of significance [93]. Those beta-blockers such as carvedilol with additional peripheral vasodilator effects also showed a similar quality of life scores to ACE-inhibitors [94]. Overall beta-1-selective agents have little if any adverse effect on quality of life [95].

Conclusions

As we enter the third millennium, beta-blocking drugs remain established in a wide variety of indications. The important indications, in terms of the numbers treated, are: Ischaemic heart disease, as a symptomatic treatment for angina pectoris and in secondary prevention after myocardial infarction, hypertension as a first line drug according to current guidelines. More recently beta-blockers have become accepted, after careful dose escalation, in the treatment of heart failure. Beta-blockers also have a useful place in glaucoma, migraine and a wide variety of other indications. They have a useful place as a prophylactic in migraine and useful applications in a variety of other conditions, although they account for relatively few prescriptions when compared to the main indications discussed above, cardiac arrhythmias, congenital obstruction of the outflow tract, pheochromocytoma, etc.

Diabetes had been regarded as a relative contra-indication, but recent evidence indicates this should no longer be the case. Similarly beta-blockers should not necessarily be withheld, when otherwise indicated, in patients with co-existent less severe peripheral vascular disease, chronic obstructive pulmonary disease without an important reversible component, although clearly a beta1-selective agent should be used.
